

Figure 8 | Why baseline stability is measured by control PSI, not by ΔPSI

Control PSI is how stable a peptide is before UBR3 is removed; ΔPSI is how much it changes when UBR3 goes. The 54 substrates were selected on ΔPSI, so splitting on it would be circular - every ΔPSI cut contains all 54 by construction.

A

PSI and ΔPSI measure different things

Baseline stability explains ~3% of the variance in UBR3 dependence - they are near-orthogonal

B

PSI 3 is a convention, not a natural boundary

Three robust modes. The data-driven split sits at 2.61; panel C shows the choice changes nothing.

C

The conclusion does not depend on where the line goes

Odds ratio stays between 42 and 88 for every cutoff from 2.0 to 3.4

D

With no cutoff at all, the motif effect stands

Logistic regression with control PSI as a continuous covariate; bars are 95% CIs
