

Chemical class × position, coloured by significance (Fisher exact)

colour = $-\log_{10} p$, Fisher exact recomputed from the same 2×2 tables

n = 20 P/G-D/E/T substrates vs n = 193 non-substrate controls carrying the same motif.

Cell text is the fold change (substrates / controls) of every cell at $p < 0.05$, followed by the star bin of its uncorrected p: * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

No depleted cell reaches $p < 0.05$ anywhere in this dataset, so every coloured cell above is an enrichment. 4 of 126 testable cells reach $p < 0.05$ uncorrected, against 6 expected by chance alone — and only Basic at 8 survives BH-FDR across all 126 cells ($q < 0.05$) — the rest is not separable from that expectation.
